## Higher Dimensional Convex Hull Algorithms

## 1 Convex hulls

### 1.0.1 Definitions

The following definitions will be used throughout. Define

- $\mathrm{S}_{d}$ : A $d$-Simplex

The simplest convex polytope in $\mathbb{R}^{d}$. A $d$-simplex is always the convex hull of some $d+1$ affinely independent points. For example, a line segment is a 1 - simplex i.e., the smallest convex subspace which contains two points. A triangle is a $2-$ simplex and a tetrahedron is a 3 - simplex.

- P: A Simplicial Polytope.

A polytope where each facet is a $d-1$ simplex. By our assumption, a convex hull in 3-D has triangular facets and in 4-D, a convex hull has tetrahedral facets.

- $\mathcal{P}$ : number of facets of $P_{i}$
- $F$ : a facet of $P$
- $R$ : a ridge of $F$
- $G$ : a face of $P$
- $f_{j}\left(P_{i}\right)$ : The number of $j$-faces of $P$. Note that $f_{j}\left(S_{d}\right)=C\binom{d+1}{j+1}$.

### 1.0.2 An Upper Bound on Time Complexity: Cyclic Polytope

Consider the curve $M_{d}$ in $\mathbb{R}^{d}$ defined as $x(t)=\left(t^{1}, t^{2}, \ldots, t^{d}\right), t \in \mathbb{R}$. Let $H$ be the hyperplane defined as $a_{0}+a_{1} x_{1}+a_{2} x_{2}+\ldots+a_{d} x_{d}=0$. The intersection of $M_{d}$ and $H$ is the set of points that satisfy $a_{0}+a_{1} t+a_{2} t^{2}+\ldots a_{d} t^{d}=0$. This polynomial has at most $d$ real roots and therefore $d$ real solutions. $\rightarrow H$ intersects $M_{d}$ in at most $d$ points. This brings us to the following definition: A convex polytope in $\mathbb{R}^{d}$ is a cyclic polytope if it is the convex hull of a
set of at least $d+1$ points on $M_{d}$.
Note the following related theorem:
A cyclic polytope has $C\binom{n}{k}(k-1)$ faces for $0 \leq k \leq \frac{d}{2}$.
For a cyclic polytope, every $d$ points creates a dimension $d-1$ face. Therefore, in $d$ dimensions, given $n$ points, there are at most $C\binom{n}{d}$ facets. Or, for dimension $d$,

Theorem $1.1 f_{j-1}=C\binom{n}{j}, j \leq \frac{d}{2}$
From this, we conclude that a convex polytope of dimension $d$ can have at most $O\left(n^{\left\lfloor\frac{d}{2}\right\rfloor}\right)$ facets. Therefore, the lower bound for finding the convex hull of a set of points in dimension $d$ is $\Omega\left(n^{\left\lfloor\frac{d}{2}\right\rfloor}\right)$ (note that for $d=2, d=3, \Omega(n \log n)$ is a stronger lower bound, not based on the size of the output).

We also get the following lemma:
Lemma 1.2 Let $P_{i}$ be a convex polytope with $n$ vertices in $\mathbb{R}^{d}$ and let $p$ be a vertex of $P$. The number of faces of $P$ which contains $p$ in their boundary plus the number of incidences among them is in $O\left(n^{\left\lfloor\frac{d-1}{2}\right\rfloor}\right)$.

An intuitive explanation is that there is a hyperplane which separates $p$ from $P$. This hyperplane cuts $P$ in a $(d-1)$-dimensional polytope with at most $n-1$ vertices where each face has $p$ in its boundary.

### 1.1 The beneath-beyond algorithm

$$
\begin{aligned}
& \text { white } \\
& \text { black -- } \\
& \text { gray }
\end{aligned}
$$

Figure 1: The beneath-beyond method. Illustration of the non-pyramidal update of the tetrahedron $A B C D$ with point $P$ being the latest addition to the convex hull.

This algorithm incrementally builds up the convex hull, keeping track of current convex hull $P_{i}$ using an incidence graph. Assume that every time a point is chosen to be added to the current convex hull, it is not in the same affine space as any of the facets of the current convex hull (see figure 2b). For instance, if the current convex hull is a tetrahedron, a new point to be added will not be coplanar with any of the faces of the tetrahedron.

Figure 2: a) Pyramidal update b) Simplifying assumption that new point is not in the affine space of any of the facets of the current convex hull.

Figure 3: Non-pyramidal update: Consider in $\mathbb{R}^{3}$, if $p_{i}$ were a light shining on the current convex hull. All the facets that the light hits (white) will have to be removed. Facets bordering these facets (gray facets) will induce new facets.

### 1.1.1 Algorithm

Given a set $S$ of $n$ points in $\mathbb{R}^{d}$,

1. Presort the points along one direction, say $x_{1}$. Let $S=\left\{p_{0}, p_{1}, \ldots, p_{n-1}\right\}$, be the input points after sorting. Process the points in increasing $x_{1}$ order.
2. Take the first $d$ points, which define a facet, as the initial hull.
3. Let $p_{i}$ be the point to be added to the hull at the $i$ th stage. Let $P_{i}$ $=\operatorname{conv}\left(p_{0}, p_{1}, \ldots, p_{i-1}\right)$ be the convex hull polytope built so far. The two kinds of hull updates are pyramidal and non-pyramidal.
(a) A pyramidal update (see figure 2a) is done when $p_{i} \notin \operatorname{aff}\left(p_{0}, p_{1}, \ldots, p_{i-1}\right)$ - when $p_{i}$ is not on the hyperplane defined by the current hull. A pyramidal update consists in adding a new node representing $p_{i}$ to the incidence graph and connecting this node to all existing hull vertices by new edges .
(b) A non-pyramidal update (see Figure 3) is done when the above condition is not met, i.e., $p_{i}$ is in the affine subspace define by the current convex hull. In this case, faces that are visible from $p_{i}$ are removed and new facets are created. Faces are each assigned a
color based on their position relative to $p_{i}$. A facet $F$ of $P_{i-1}$ is colored black or white depending on whether $F$ is seen by $p_{i}$. A facet $F$ is

- White iff the hyperplane containing $F$ separates $p_{i}$ and $P_{i-1}$
- Black otherwise

A lower dimensional face $G$ is colored either white, black, or gray, depending on the colors of the faces of which it is a subface. A face $G$ is

- White if it is a subface of only white faces
- Black if it is a subface of only black faces
- Gray otherwise

White faces are visible from $p_{i}$. Black faces are not visible from $p_{i}$. Gray faces are the borders between visible and non-visible faces. The updated hull is obtained as follows. If a face $G$ (includes facets and lower dimensional faces) is colored
i. Black $\rightarrow G$ remains in the convex hull
ii. Gray $\rightarrow G$ remains in the convex hull and $G$ induces a new face $G^{\prime}$ with $p_{i}$. $G^{\prime}=C H\left(G \bigcup p_{i}\right)$.
iii. White $\rightarrow G$ is deleted

Figure 4:

### 1.1.2 Algorithm Analysis

Define

- $\mathcal{P}_{i}$ : number of faces of $P_{i}$
- $I_{i}$ : number of faces created in updating $P_{i-1}$ to include $p_{i}$ (note that since each gray face induces a new face, this is also the number of gray faces).
- $D_{i}$ : number of faces that get deleted (note that this is also the number of white faces).

If we use a hyperplane $H$ to cut the point $p_{i}$ off from the rest of the polytope we can use 1.1 to find an upper bound on the number of new faces - the upper bound on the number of $d-2$ faces
$f_{d-2}\left(P_{i}\right)=O\left(i^{\left\lfloor\frac{d-1}{2}\right\rfloor}\right)$ (see Lemma 1.2).

## - Pyramidal Update Time Complexity Analysis

Realize that the time complexity for a pyramidal update is linear in the number of faces. Therefore, the time complexity is $O\left(I_{i}\right)$.

- Non-pyramidal Update Time Complexity Analysis

To compute time complexity of a non-pyramidal update, consider the two following facts

1. One of the facets containing $p_{i-1}$ must be white.
2. White facets form a connected set in the graph in which a facet is represented by a node and a ridge is represented by an edge

Therefore, we can compute the time complexity of the algorithm as

1. $O\left(i^{\lfloor(d-1) / 2\rfloor}\right)$ : Identify one white facet by considering facets containing $p_{i-1}$ (note the set of facets incident upon $p_{i}$ has dimension $d-1)$.
2. $O\left(D_{i}+I_{i}\right)$ : Determine the remaining white facets using DFS through the incidence graph.
3. $O\left(D_{i}+I_{i}\right)$ : Determine all the white and gray faces using DFS.
4. $O\left(D_{i}\right)$ : Delete all white faces.
5. $O\left(I_{i}\right)$ : Make new faces from gray faces.

The total amount of work done during non-pyramidal updates is $\sum_{i<n} O\left(D_{i}+\right.$ $I_{i}$ ). Since only faces which have already been inserted can be deleted we know that $\sum_{i<n} O\left(D_{i}+I_{i}\right) \leq \sum_{i<n} O\left(I_{i}\right)$. So we can bound the time spent if we can bound the total number of faces inserted.

How can we bound $I_{i}$ ? Note that $P_{i}$ contains at most $i$ vertices, since only $i$ points have been processed. Imagine taking a hyperplane and using it to cut $p_{i}$ off from the rest of the polytope. The remaining polytope would be a $d-1$ dimensional polytope, which can have at most $O\left(i^{\lfloor(d-1) / 2\rfloor}\right)$ faces (see Lemma 1.2). Thus the time complexity of the incremental algorithm is:

$$
\sum_{i<n} O\left(D_{i}+I_{i}\right) \leq \sum_{i<n} O\left(I_{i}\right) \leq \sum_{i<n} O\left(i^{\lfloor(d-1) / 2\rfloor}\right)=O\left(n^{\lfloor(d+1) / 2\rfloor}\right)
$$

The presorting step takes time $O(n \log n)$, so the overall time complexity is $O\left(n \log n+n^{\lfloor(d+1) / 2\rfloor}\right)$. This is the optimal worst case complexity for even $d$.

### 1.2 The Gift-Wrapping method

Figure 5: Gift-wrapping. Point $D$ is interior to the tetrahedron formed by points $A, B, C$, and $P$, and is therefore not on the convex hull. We start with the triangle $A B C$ and gift-wrap around the edge $B C$. The point $P$ and facet $B C P$ is added to the hull. Next, we gift-warp around edge $A C$ and add facet $A C P$ to the hull.

This algorithm was proposed by Chand and Kapur in 1970 and is discussed in [1], pg. 125-130. A rough sketch in $\mathbb{R}^{3}$ is presented here. Define

- $\mathcal{T}$ : a "pool" of candidate subfacets for gift-wrapping

The important rules which will be used are:

- Every ridge is contained in exactly two facets.
- Every edge joins exactly two points.
- Given a facet $F$ and a ridge $R$, one can find the "other" facet $F^{\prime}$ that contains $R$ in $O(n)$ time.

### 1.2.1 Algorithm

1. Find some facet $F$ and call its ridges "open" ridges
2. Put open ridges in pool $\mathcal{T}$
3. While $\mathcal{T}$ is not empty

Figure 6: Illustration of discovering facets using the Gift-Wrapping method.

- $O(n)$ : Giftwrap over $R$

Determine, among all $p_{i} \in S$ which are not vertices of $F$, the point $p^{\prime}$ such that all other points are on one side of the hyperplane $\operatorname{aff}\left(R \cup\left\{p^{\prime}\right\}\right)$.

- $O(c)$ : Update pool of open ridges

Add edges of newly discovered face to $\mathcal{T}$.
The gift-wrapping step is shown for a 3-D case in Figure 5.

### 1.2.2 Algorithm Analysis

Let $\mathcal{P}$ be the number of facets of the convex hull of the $n$ input points. Then the time taken by the algorithm is $O(n \mathcal{P})$. Thus the time taken by this algorithm is sensitive to the size of the output. However, also note that we can discover the same facet multiple times since each facets has three ridges. Note that $\mathcal{P}$ can be as large as $n^{\lfloor d / 2\rfloor}$, giving a worst-case complexity of $O\left(n^{\lfloor(d+2) / 2\rfloor}\right)$.

### 1.3 Seidel's shelling algorithm

Figure 7: Shelling of a polytope. a) $e_{1}, e_{2}, e_{3}, e_{4}, e_{5}$ is a shelling of the convex polygon but $e_{1}, e_{2}, e_{4}, e_{5}, e_{3}$ is not. b) $A B C, A B D, B D P, B P C, A P C, A P D$ is a shelling, while $A B C, P B C, A D P, D B P, A P C, A B D$ is not, since, for instance, the intersection of facet $A D P$ with the union of facets $A B C$ and $P B C$ does not have any edge in it. c) $A B C D, A B E F, C D G H, E F G H, B C G F, A E H D$ is not a shelling because the intersection of $E F G H$ with the union of facets $A B C D, A B E F$, and $C D G H$ consists of the set of edges $E F, G H$ which does not constitute a legal sub-shelling of the facet $E F G H$.

The two previous algorithms for the higher dimensional convex hull problem, the Beneath-Beyond method and the Gift-Wrapping algorithm have complexities of $O\left(n^{\lfloor(d+1) / 2\rfloor}\right)$ and $O(n \mathcal{P})$ respectively. Depending on output size, gift-wrapping can be as bad as $O\left(n^{\lfloor(d+2) / 2\rfloor}\right)$. Seidel's shelling algorithm [4] has a complexity of $O\left(n^{2}+\mathcal{P} \log n\right)$. In the worst case $\mathcal{P}=n^{\left\lfloor\frac{d}{2}\right\rfloor}$, so the time complexity is $O\left(n^{2}+n^{\left\lfloor\frac{d}{2}\right\rfloor} \log n\right)$, which is the best bound known for odd $d>3$.

### 1.3.1 The shelling of a polytope

The shelling method works by traveling along a line and determining the facets of the convex hull as they become visible.

Consider a $d$-polytope $P$ with $n$ faces $F_{1}, F_{2}, \ldots F_{n}$. Imagine traveling along a directed straight line $L$ that intersects the interior of $P$. Begin at a point on $L$ that is in the interior of $P$. Continue until you pass through

Figure 8: The shell is incrementally created so that it is fully connected. a) The horizon of the shell. b) The next facet to be discovered can intersect the horizon in one of two ways - at multiple ridges (left) or at a single ridge (right).
some facet $F$. This facet $F$ is the first in the shelling order. Continue moving away from $P$ along $L$ and more facets will become visible. The order in which these facets appear is the shelling order. When no more facets are visible, jump back (or "move through infinity") to the "beginning" of $L$. All the facets of $P$ that were not visible before are now visible. Still moving along $L$, but now towards $P$, facets will become invisible. The order in which they disappear constitutes the second part of the shelling order.

A shelling of a $d$-polytope $P$ is an ordering of the facets of $P$, say $F_{1}, F_{2}, \ldots, F_{m}\left(m=f_{d-1}(P)\right.$, the number of $d-1$ faces or facets of $\left.P\right)$, so that for each $i, 1 \leq i \leq n$,

$$
F_{i} \cap\left(\bigcup_{j<i} F_{j}\right)
$$

yields the non-empty initial portions of some shelling of $P_{i}$.

### 1.3.2 Linear Programming for Shelling

The shelling line $L$ is parameterized by $x(t)=-\mathbf{a} / t,-\infty<t<+\infty$. The vector ais the direction of $L$.
We can use linear programming to determine for every $p \in \mathrm{~S}$ whether $p$ is a vertex of $P$ and, if it is, the first facet in the shelling that contains $p$. Let $H_{p}$ be the hyperplane that contains that facet. All such $H_{p}$ 's are included in
$\mathbf{H}_{i} . H_{p}$ is such that $\forall q \in \mathrm{~S}, q \in H_{p}^{+}$and $H_{p}$ intersects $L$ "first." We need to find $\mathbf{n}=\left(n_{1}, n_{2}, \ldots, n_{d}\right)$ such that:

- $\langle q-p, \mathbf{n}\rangle \geq 0$

The hyperplane through $p$ keeps all $q \in \mathrm{~S}$ to one side. Recall that $\langle a, b\rangle=|a||b| \cos (\theta)$. Therefore, $\langle a, b\rangle \geq 0$ if $\frac{-\pi}{2} \leq \theta \leq \frac{-\pi}{2}$. We can insist that $\langle p, \mathbf{n}\rangle=1$.

- $\left\langle\frac{-\mathbf{a}}{t}-p, \mathbf{n}\right\rangle=0$. Remember that $x(t)=-\frac{\mathbf{a}}{t}$.
- Combining the above items:

$$
\begin{aligned}
& \left\langle\frac{-\mathbf{a}}{t}-p, \mathbf{n}\right\rangle=0 \\
& \left\langle\frac{-\mathbf{a}}{t}, \mathbf{n}\right\rangle+\langle-p, \mathbf{n}\rangle=0 \\
& \left\langle\frac{-\mathbf{a}}{t}, \mathbf{n}\right\rangle=\langle p, \mathbf{n}\rangle \\
& \left\langle\frac{-\mathbf{a}}{t}, \mathbf{n}\right\rangle=1 \\
& \frac{-1}{t}\langle\mathbf{a}, \mathbf{n}\rangle=1 \\
& t=-\langle\mathbf{a}, \mathbf{n}\rangle
\end{aligned}
$$

That is, $x(t)$ is on the same hyperplane as $p$.
So the linear program is: $t=-\langle\mathbf{a}, \mathbf{n}\rangle,\langle p-q, \mathbf{n}\rangle \geq 0,\langle p, \mathbf{n}\rangle=1$ If for some $p$, the LP is infeasible, then $p$ is interior to $\mathrm{CH}(\mathrm{S})$. Otherwise, we can discover the first facet in the shelling order containing $p$.

### 1.3.3 A straight line shelling

Define

- $L$ : A shelling line
- $T$ : A set of horizon peaks
- $\mathbf{H}_{i}$ : A set of hyperplanes
- $H$ : A single hyperplane
- Horizon face: A face $G$ of $f c h$ a horizon face at (time) $t$ iff $G$ is contained in two facets $F_{i}$ and $F_{j}$ of $f c h$ with $t_{i}<t$ and $t_{j} \geq t$. Thus a horizon face is part of one face already seen along the shelling line and one face not yet seen.
- $G$ : Horizon ridge: $\mathrm{A}(d-2)$-face
- $g$ : Horizon peak: A $(d-3)$-face
- Horizon (at time t): The set of all horizon faces at time $t$.

Figure 9: Shelling of a polytope. a) Shelling line. b) Determination of next facet in shelling order. Assume that the shelling order is (ABC, ACD, BCE, $\mathrm{CDE}, \mathrm{ABD}, \mathrm{BDE})$. Then, after $A B C$ has been discovered, the next facet $A C D$ has only one ridge $(A C)$ intersecting with $A B C$. The next facet $B C E$ has also just one ridge $(B C)$ intersecting with the union of the first two facets. The fourth facet $C D E$ has two ridges, $C D$ and $C E$ intersecting with the union of the first three facets and these ridges along with the vertex $C$ uniquely determine the facet $C D E$.

### 1.3.4 Using shelling to construct facets of the convex hull

Assumptions: No $d+1$ points lie in a common hyperplane. This assumption implies that $P$, the convex hull, is a simplicial $d$-polytope, i.e., all facets of $P$ are ( $d-1$ )-simplices.

### 1.3.5 Algorithm

1. For each point $p \in S$ solve a linear program with $n-1$ constraints and $d-1$ variables.
(a) If the program is infeasible then eliminate $p$ from S . It cannot be a vertex of $\mathrm{CH}(\mathrm{S})$.
(b) If it is feasible then enter in the priority queue the time $t_{p}$ and the set of points $Q_{p}$ that when unioned with $p$ that formed the hyperplane.
2. Let $t$ be the minimum value in the priority queue. Report the facet corresponding to $t$ as the first facet. Delete the $t_{p}$ values from the priority queue.

Figure 10: a) Given a point $p$, the linear program finds the point $q_{5}$ whose facet with $p$ interesects the shelling line "first" and keeps all other points to one side $\left(\left\langle q_{4}-p, \mathbf{n}\right\rangle>0 \leftrightarrow \cos (\theta)>0\right)$. b) Illustration of discovering facets in the shelling order.
3. Process each time in the priority queue. For each time $t$, there is an associated facet $F$ to find. This facet can join the existing horizon in one of two ways: For each $t$ in the priority queue, the still unknown facet will have order.
(a) $F$ intersects the horizon in more than 1 ridge. Therefore, $F$ contains some horizon peak $G$ and its two horizon ridges $R_{1}, R_{2}$. But, $\operatorname{dim}\left(R_{1} \cup R_{2}\right)=\operatorname{dim}\left(R_{1}\right)+\operatorname{dim}\left(R_{2}\right)-\operatorname{dim}\left(R_{1} \cap R_{2}\right)$ (note $R_{1} \cap R_{2}=G=(d-2)+(d-2)-(d-3)=d-1$ (a hyperplane)
(b) The intersection consists of exactly one horizon ridge $G$. In this case we cannot deduce $F_{i}$ from the structure of the horizon. However, $F_{i}$ must contain a vertex $p \in \mathrm{~S}$ that is not contained in $G$. Also, $p$ is not contained in any $F_{j}$ with $j<i$. In other words, $F_{i}$ is the first facet in the shelling that contains $p$.

For the algorithm, We proceed as follows. Find the minimum time $t$ and its associated data. If
(a) There is a single point $p$ with the minimum time. This corresponds the $F_{i}$ intersecting the horizon along a single ridge. Report $Q_{p} \cup p$ as the next facet.

In this case, the horizon changes by adding a new peak. We therefore have to compute the hyperplanes generated by this peak and its neighbor peaks and add these new hyperplanes (ie their times $t$ to the priority queue.
(b) There are multiple points with the minimum time. This corresponds to $F_{i}$ intersecting the horizon along multiple ridges and the multiple points are the horizon peaks. The union of the horizon peaks is the next facet.
The horizon has been updated by adding a new ridge. We use linear programming to find the point $p$ that with that ridge will create facet of $P$. We add this hyperplane to the priority queue.

### 1.3.6 Algorithm Analysis

If the dimension $d$ is fixed, each of the $n$ linear programs can be solved in $O(n)$ time using Meggido's algorithm [5]. Thus the first step can be performed in $O\left(n^{2}\right)$ time. Each time a facet is reported the priority queue (of size at most $\left.n^{\lfloor d / 2\rfloor}\right)$ is updated. For fixed $d$, this takes time $O(F \log n)$ where $\mathcal{P}$ is the number of facets reported. Thus the overall complexity is $O\left(n^{2}+\mathcal{P} \log n\right)$. If $\mathcal{P}$ is superlinear, this beats gift-wrapping. In the worst case, it is the best algorithm for odd $d$ but is not provably optimal.
