Compiling Pattern Matching to good Decision Trees

Luc Maranget
INRIA
Luc.maranget@inria.fr

Abstract
We address the issue of compiling ML pattern matching to efficient
decisions trees. Traditionally, compilation to decision trees is op-
timized by (1) implementing decision trees as dags with maximal
sharing; (2) guiding a simple compiler with heuristics. We first de-
sign new heuristics that are inspired by necessity, a notion from
lazy pattern matching that we rephrase in terms of decision tree
semantics. Thereby, we simplify previous semantical frameworks and
demonstrate a direct connection between necessity and decision
tree runtime efficiency. We complete our study by experiments,
showing that optimized compilation to decision trees is competi-
tive. We also suggest some heuristics precisely.

Categories and Subject Descriptors D.3.3 [Programming Lan-
guages]: Language Constructs and Features—Patterns

General Terms Design, Performance, Sequentiality.

Keywords Match Compilers, Decision Trees, Heuristics.

1. Introduction
Pattern matching certainly is one of the key features of functional
languages. Pattern matching is a powerful high-level construct that
allows programming by directly following case analysis. Cases to
match are expressed as “algebraic” patterns, i.e. terms. Definitions
by pattern matching are roughly similar to rewriting rules: a series
of rules is defined; and execution is performed on subject values
by finding rules who left-hand side is matched by the value. With
respect to plain term rewriting, the semantics of ML simplifies
two issues. First, matches are always attempted at the root of the
subject value. And, second, there are no ambiguities as regards the
matched rule.

All ML compilers translate the high level pattern matching
definitions into low-level tests, organized in matching automata.
Matching automata fall in two categories: decision trees and back-
tracking automata. Compilation to backtracking automata has been
introduced by Augustsson (1985). The primary advantage of the
technique is a linear guarantee for code size. However, backtracking
automata may backtrack and, at the occasion, they may scan
subterms more than once. As a result, backtracking automata are
potentially inefficient at runtime. The optimizing compiler of Le
Fessant and Maranget (2001) somehow alleviates this problem.

In this paper we study compilation to decision tree, whose
primary advantage is never testing a given subterm of the subject
value more than once (and whose primary drawback is potential
code size explosion). Our aim is to refine naive compilation to
decision trees, and to compare the output of such an optimizing
compiler with optimized backtracking automata.

Compilation to decision can be very sensitive to the testing
order of subject value subterms. The situation can be explained
by the example of an human programmer attempting to translate a
ML program into a lower-level language without pattern matching.
Let T be the following function\textsuperscript{1} defined on triples of booleans :

\begin{verbatim}
let f x y z = match x, y, z with
| _, F, T -> 1
| F, T, _ -> 2
| _, F, _ -> 3
| _, _, T -> 4
\end{verbatim}

Where T and F stand for true and false respectively.

Apart from preserving ML semantics (e.g. T F T should evaluate
to 2), the game has one rule: never test x, y or z more than
once. A natural idea is to test x first, i.e to write:

\begin{verbatim}
let f x y z = if x then f_TXX y z else f_FXX y z
\end{verbatim}

Where functions f_TXX and f_FXX are still defined by pattern
matching:

\begin{verbatim}
let f_TXX y z = match y, z with
| F, T -> 1
| _, F -> 3
| _, _, T -> 4
\end{verbatim}

\begin{verbatim}
let f_FXX y z = match y, z with
| T, _ -> 2
| _, F -> 3
| _, _, T -> 4
\end{verbatim}

Compilation goes on by considering y and z, resulting in the fol-
lowing low-level f1:

\begin{verbatim}
let f1 x y z =
  if x then
    if y then
      if z then 4 else 3
    else
      if z then 1 else 3
  else
    if y then 2
  else
    if z then 1 else 3
\end{verbatim}

We can do a little better, by elimination of the common subexpression
if z then 1 else 3 as advised by many and described precisely

But we can do even better, by first testing y, and x first when y
is true, resulting in the second low-level f2:

\begin{verbatim}
let f2 x y z =
  if y then
    if x then
      if z then 4 else 3
    else
      if z then 1 else 3
  else
    if y then 2
  else
    if z then 1 else 3
\end{verbatim}

\textsuperscript{1} We use OCaml syntax.

[Copyright notice will appear here once 'preprint' option is removed.]
if $y$ then
  if $z$ then 4 else 3
else if $z$ then 1 else 3

Choosing the right subterm to test first is the task of match-compiler heuristics.

In this paper we tackle the issue of producing $f_2$ and not $f_1$ automatically. We do so first from the point of view of theory, by defining necessity in terms of strict matching. Necessity has been defined in the context of lazy pattern matching: a subterm (of subject values) being needed, when its reduction is mandatory for the lazy semantics of matching to yield a result. Instead, we define necessity by universal quantification over decision trees. Necessity provides inspiration and justification for a few new heuristics which we study experimentally.

2. Simplified source language

Most ML values can be defined as ground terms over some signatures. Signatures are introduced by (algebraic) data type definitions. We leave data types definition implicit. In other words, we assume that constructors are defined elsewhere, and consider the values:

$$v ::= \begin{cases}
    c(v_1, \ldots, v_n) & a \geq 0 \\
    \frac{v}{\Lambda} & \text{class discipline}
\end{cases}$$

An implicit typing discipline for values is assumed. In particular, arities are obeyed, and, given a constructor $c$, one knows which signature it belongs to. In examples, we systematically omit $(\cdot)$ after constants constructors, i.e. we write $\mathbf{nil}$, $\mathbf{true}$, $0$, etc.

We also consider the usual occurrences in terms. Occurrences are sequences of integers that describe the positions of sub-terms. More precisely an occurrence is either empty, written $0$, or is an integer $k$ followed by an occurrence $\omega$, written $o\cdot k$. Occurrences are paths to subterms, in the following sense:

$$\frac{v}{\Lambda} = v$$

Following common practice we omit the terminal $\Lambda$ of non-empty occurrences. We assume familiarity with the standard notions over occurrences: prefix (i.e. $o_1$ is a prefix of $o_2$ when $v/o_2$ is a sub-term of $v/o_1$), incompatibility (i.e. $o_1$ and $o_2$ are incompatible when $o_1$ is not a prefix of $o_2$ nor $o_2$ is a prefix of $o_1$). We consider the leftmost-outermost ordering over occurrences that corresponds to the standard lexicographic ordering over sequences of integers, and also to the standard prefix depth-first ordering over subterms.

We use the following simplified definition of patterns:

$$p ::= \begin{cases}
    \text{wildcard} & c(p_1, \ldots, p_n) \\
    \text{constructor pattern} (a \geq 0) & \frac{p_1 \ldots p_n}{p_1} \\
    \text{or-pattern} & \frac{p_1 \mid p_2}{o\cdot k}
\end{cases}$$

The main simplification is replacing all variables with wildcards. In the following we shall consider pattern vectors, $\vec{p}$ which are sequences of patterns $(p_1 \cdots p_n)$, pattern matrices $\vec{P}$, and clause matrices $\vec{P} \to A$:

$$\vec{P} \to A = \begin{pmatrix}
    p_1 \cdots p_m & a^1 \\
    p_2^1 \cdots p_m^1 & a^2 \\
    \vdots & \vdots \\
    p_1^m \cdots p_m^m & a^m
\end{pmatrix}$$

By convention, vectors are of size $n$, matrices are of size $n \times m$ ($n$ is the width and $m$ is the height). Pattern (and clause) matrices are natural and convenient in the context of pattern matching compilation. Indeed they express the simultaneous matching of several values. In clauses, actions $a^j$ are integers. We sometime write row $j$ of matrix $\vec{P}$ as $\vec{p}^j$.

Clause matrices are an abstraction of pattern matching expressions as can be found in ML programs. Simplification consists in replacing the expressions of ML by integers, which are sufficient to our purpose. Thereby, we avoid the complexity of describing the full semantics of ML, still preserving a decent level of precision.

2.1 Semantics of ML matching

Generally speaking, value $v$ is an instance of pattern $p$, written $p \preceq v$, when there exists a substitution $\sigma$, such that $\sigma(p) = v$.

In the case of linear patterns, the above mentioned instance relation is equivalent to the following inductive definition:

$$\frac{p_1 \mid p_2}{v} \iff v \preceq p_1 \vee p_2 \preceq v$$

One can note that the last line above defines the instance relation for vectors.

We also give an explicit definition of the relation "value $v$ is not an instance of pattern $p$", written $p \not\preceq v$:

$$\frac{p_1 \mid p_2}{v} \iff v \not\preceq p_1 \vee p_2 \not\preceq v$$

For the values and patterns that we have considered so far, relation $\not\preceq$ is the negation of $\preceq$. However this will not remain true, and we rather adopt a non-ambiguous notation.

**Definition 1** (ML matching). Let $P$ be a pattern matrix matrix of width $n$ and height $m$. Let $\vec{v}$ be a value vector of size $n$. Let $j$ be a clause index ($1 \leq j \leq m$).

Row $j$ of $P$ filters $\vec{v}$ in the ML sense, when the following two propositions hold:

1. Vector $\vec{v}$ is an instance of $\vec{p}^j$, (written $\vec{p}^j \preceq \vec{v}$).
2. For all $j' \leq j$, $1 \leq j' < j$, vector $\vec{v}$ is not an instance of $\vec{p}^{j'}$ (written $\vec{p}^{j'} \not\preceq \vec{v}$).

Furthermore, if we complete $P$ into a clause matrix $P \to A$, and that row $j$ of $P$ filters $\vec{v}$, we write:

$$\text{Match}[\vec{v}, P \to A] \overset{\text{def}}{=} a^j$$

2.2 Matrix decomposition

The compilation process transforms clause matrices by the means of two basic "decomposition" operations, defined in Figure 1. The first operation is specialization by constructor $c$, written $S(c, P \to A)$, (left of Figure 1) and the second operation computes a default matrix, written $D(P \to A)$ (right of Figure 1). Both transformations apply to the rows of $P \to A$, taking order into account, and yield the rows of the new matrices.

Specialization by constructor $c$ retains the rows whose first pattern $p_1^j$ admits all values $c(v_1, \ldots, v_n)$ as instances. For instance, given the following clause matrix:

$$P \to A \overset{\text{def}}{=} \begin{pmatrix}
    \square & \rightarrow & \rightarrow & \rightarrow \\
    \rightarrow & \square & \rightarrow & \rightarrow \\
    \rightarrow & \rightarrow & \rightarrow & \rightarrow
\end{pmatrix}$$
### Decision Tree Structure

A decision tree structure is clearly visible, with multi-way tests being of a constructor and of decision trees, written as trees. They are not part of tree structure strictly speaking. Nodes end with an optional switch clause lists (\(\mathcal{L}\)).

Throughout the paper, we shall assume well formed switches in the following sense:

1. Constructors \(c_k\) belong to the same signature, and are pairwise distinct.
2. The default clause is present, if and only if the set \(\{c_1, \ldots, c_s\}\) is not a complete signature.

For the sake of precise proofs, we give a semantics for evaluating decision trees (Figure 2). Decisions trees are evaluated with respect to a stack of values. The stack initially holds the subject value. Evaluation is expressed by judgments \(\overline{v} \vdash A \rightsquigarrow k\) reading: evaluating tree \(A\) w.r.t. stack \(\overline{v}\) yields the action \(k\). Evaluation is over at tree leaves (rule \textsc{Match}). The heart of the evaluation is the evaluation of switch nodes, described by the two rules \textsc{SwitchConstr} and \textsc{SwitchDefault}. Clause selection is performed by the auxiliary rules \textsc{Found}, \textsc{Default} and \textsc{Cont}. These rules express nothing more than search in an association list. Since switches are well-formed, the search always succeeds. It is to be noticed that switch always examine the value on top of the stack, i.e. value \(v_1\). It is also to be noticed that the occurrence \(o\) in \textsc{Switch}_{\{o\}}(\mathcal{L}) serves no purpose during evaluation. The two rules \textsc{SwitchConstr} and \textsc{SwitchDefault} differ significantly as regards what is made of the arguments of \(v_1\), they are either pushed or ignored, in all cases the value examined is popped from the stack. Decision trees feature a node that performs an operation of the stack: \textsc{Swap}, \(\{A\}\) (rule \textsc{Swap}). The trick allows the examination of any value \(v_i\) from the stack, by the combination \textsc{Swap}, (\textsc{Switch}_{\{l\}}(\mathcal{L}))

Finally, since there is no rule to evaluate \textsc{Fail} nodes, match failures and all other errors (such as induced by ill-formed stacks) are not distinguished by the semantics. Namely, our simple setting spares the burden of giving precise semantics to errors.

#### 4. Compilation Scheme

The compilation scheme distinguishes constructor patterns and wildcards. To take or-patterns into account we define \textit{generalized constructor patterns}.

\[
\begin{align*}
\quad & q \quad \text{(p's are any patterns)} \\
\quad & (q | p) \quad \text{(p is any pattern)}
\end{align*}
\]

In other words a generalized constructor pattern is either a constructor pattern or a or-pattern whose leftmost alternative is a constructor pattern.

In all the following developments, \((\_ | p)\) will behave exactly as \_ does. Hence, to alleviate notations a bit, we assume that a preprocessing phase normalizes patterns, so that any pattern is either a generalized constructor pattern or a wildcard.

Compilation scheme \(\mathcal{CC}\) is described as a non-deterministic function that takes two arguments, a vector of occurrences \(\overline{o}\), and a clause matrix. The occurrences of \(\overline{o}\) define the fringe, that is, the subterms of the subject value that need to be checked against the patterns of \(P\) to decide matching. The fringe \(\overline{v}\) is the compile-time counterpart of the stack \(\overline{v}\) used during evaluation. More precisely we have \(v_i = v/\alpha_i\) where \(v\) is the subject value.

Compilation is defined by cases as follows.

1. If matrix \(P\) has no rows (i.e. \(n = m = 0\)) then matching always fails, since there is no row to match.

\[
\mathcal{CC}(\overline{0}, \emptyset \to A) \overset{\text{def}}{=} \text{Fail}
\]
Auxiliary rules for switch clause selection

\[
\begin{align*}
\text{(Found)} & \quad c \vdash c.r; L \leftarrow c.r \quad \text{(Default)} & \quad c \vdash *; A \leftarrow *; A \\
\text{(Switch)} & \quad (v_1 \ldots v_1 \ldots v_n) \vdash A \leftarrow k \quad \text{(SwitchConstr)} & \quad (c_1 \ldots c_n) \vdash c.r \leftarrow (c_1 \ldots c_n) \vdash \text{Switch}_{\text{c}}(L) \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(SwitchDefault)} & \quad c \vdash L \leftarrow *; A \quad (v_2 \ldots v_n) \vdash \text{Switch}_{\text{c}}(L) \leftarrow k \\
\text{(Cont)} & \quad c \neq c' \quad c \vdash c'/*; A
\end{align*}
\]

\[
\begin{align*}
\text{(Match)} & \quad \vec{o} \vdash \text{Leaf}(k) \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(Swap)} & \quad (v_1 \ldots v_1 \ldots v_n) \vdash A \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(SwitchConstr)} & \quad (c_1 \ldots c_n) \vdash c.r \leftarrow (c_1 \ldots c_n) \vdash \text{Switch}_{\text{c}}(L) \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(SwitchDefault)} & \quad c \vdash L \leftarrow *; A \quad (v_2 \ldots v_n) \vdash \text{Switch}_{\text{c}}(L) \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(Cont)} & \quad c \neq c' \quad c \vdash c'/*; A
\end{align*}
\]

\[
\begin{align*}
\text{(Match)} & \quad \vec{o} \vdash \text{Leaf}(k) \leftarrow k
\end{align*}
\]

\[
\begin{align*}
\text{(Swap)} & \quad (v_1 \ldots v_1 \ldots v_n) \vdash A \leftarrow k
\end{align*}
\]

Auxiliary rules for switch clause selection

2. If the first row of \( P \) exists and is made of wildcards, then matching always succeeds and yields the first action.

\[
\begin{align*}
\text{CC}(\vec{o}, (p^1_1 \ p^2_1 \ \cdots \ p^m_1 \ a^0 \ a^1 \ a^2)) & \overset{\text{def}}{=} \text{Leaf}(a^1) \\
\text{CC}(\vec{o}, (p^1_1 \ p^2_1 \ \cdots \ p^m_1 \ a^0)) & \overset{\text{def}}{=} \text{Leaf}(a^0)
\end{align*}
\]

In particular, this case applies when there are rows \( m > 0 \) and no columns \( n = 0 \).

3. In all other cases, matrix \( P \) has rows \( m > 0 \) and columns \( n > 0 \) and there exists at least one column of which at least one pattern is not a wildcard. We select one such column \( i \).

(a) Let us first consider the case when \( i = 1 \). We define \( \Sigma_1 \) the set of the head constructors of the patterns in column 1.

\[
\Sigma_1 = \cup_{1 \leq j \leq m} \mathcal{H}(p^j_1)
\]

\[
\mathcal{H}(\omega) \overset{\text{def}}{=} \emptyset \quad \mathcal{H}(c(\ldots)) \overset{\text{def}}{=} \{ c \}
\]

\[
\mathcal{H}(q_1 \mid q_2) \overset{\text{def}}{=} \mathcal{H}(q_1) \cup \mathcal{H}(q_2)
\]

Let \( c_1, c_2, \ldots, c_{\Sigma_1} \) be the elements of \( \Sigma_1 \). By hypothesis, \( \Sigma_1 \) is not empty \( z \geq 1 \). For each constructors \( c_k \) from \( \Sigma_1 \), we perform the following inductive call that yields decision tree \( A_k \).

\[
A_k \overset{\text{def}}{=} \text{CC}((a_1 \cdot \ldots \cdot a_{\Sigma_1} \cdot a_{\Sigma_1 + 1} \cdot \ldots \cdot a_n), S(c_k, P \rightarrow A))
\]

The notation \( a \) above stands for the arity of \( c_k \). Notice that \( a_1 \) disappears from the occurrence vector, being replaced by the occurrences \( a_1 \cdot \ldots \cdot a_{\Sigma_1} \). The decision trees \( A_k \) are regrouped into a clause list \( L \).

\[
L \overset{\text{def}}{=} c_1; A_1 \cdots c_{\Sigma_1}; A_{\Sigma_1}
\]

If \( \Sigma_1 \) is not a complete signature, an additional recursive call is performed on the default matrix. The switch clause is completed accordingly:

\[
A_D \overset{\text{def}}{=} \text{CC}((a_1 \cdot \ldots \cdot a_n), D(P \rightarrow A))
\]

\[
L \overset{\text{def}}{=} c_1; A_1 \cdots c_{\Sigma_1}; A_{\Sigma_1} \cdot A_D
\]

Finally compilation yields a switch that tests occurrence \( o_1 \):

\[
\text{CC}(\vec{o}, P \rightarrow A) \overset{\text{def}}{=} \text{Switch}_{o_1}(L)
\]

(b) If \( i > 1 \) then we swap columns 1 and 1 both in \( \vec{o} \) in \( P \), yielding \( \vec{o'} \) and \( Q' \) respectively. We then compute \( A' = \text{CC}(\vec{o'}, P' \rightarrow A) \) as above, yielding decision tree \( A' \), and we define:

\[
\text{CC}(\vec{o}, P \rightarrow A) \overset{\text{def}}{=} \text{Switch}_{o_1}(L)
\]

Notice that the “function” \( \text{CC} \) is non-deterministic because of the unspecified choice of \( i \).

Compilation to decision tree is a simple algorithm. Inductive step 3 above selects a column \( i \) (i.e. an occurrence \( o_i \) from the subject value), the head constructor of \( v/o \) is examined and compilation goes on, considering all possible constructors.

One crucial property of decision trees is that no subterm \( v/o \) is examined more than once. The property is made trivial by our decision tree semantics—evaluation of a switch pops the examined value. It should also be observed that if the components \( o_i \) of \( \vec{o} \) are pairwise incompatible, then the property still holds for recursive calls.

We have already remarked that the occurrence \( o \) that decorates a switch node \( \text{Switch}_{o}(L) \) plays no part during evaluation. We can now further remark that occurrences \( o_i \) are not necessary to define the compilation scheme \( \text{CC} \). Hence, we often omit occurrences, writing \( \text{CC}(P \rightarrow A) \) and \( \text{Switch}(L) \). At the moment occurrences are here to give extra intuition on decision trees: they tell which subterm of the subject value is examined by a given \( \text{Switch}_{o}(L) \) node.

We define a “naive” compilation by the trivial choice function that selects the first column of \( P \). Formally, this requires extending recursive step 3 a bit, by allowing set \( \Sigma_1 \) to be empty. In that case, only the default matrix is considered and \( \text{Switch}_{o_1}(*) \cdot A_D \) reduces to \( A_D \). Alternatively, one may also consider a naive choice function that selects the column index \( i \) such that \( o_i \) is minimal for the leftmost-outermost ordering on occurrences, amongst the occurrences \( o_k \) such that at least one pattern \( p^j_k \) is not a wildcard. It is not difficult to see, although tedious to prove, that both naive compilers produce the same decision trees.

A real pattern matching compiler can be written by following compilation scheme \( \text{CC} \). There are differences though. First, the real compiler targets a language more complex than simple decision trees. More precisely, the occurrence vector \( \vec{o} \) is replaced by a variable vector \( \vec{x} \) and the target language has explicit local bindings in place of a simple stack. Furthermore, real multi-way tests are more flexible: they operate on any variable (not only on top of stack). Second, decision trees produced by the real compiler are implemented as dags with maximal sharing—see Pettersson (1992) for a detailed account of this technique.
In spite of these differences, our simplified decision trees offer a
good approximation of actual matching automata, especially if we
represent them as pictures, while omitting Swap_\(a\) nodes.

5. Correctness
The main interest for having defined decision tree semantics will
appear later, while considering semantical properties more subtle
than simple correctness. Nevertheless, we state a correctness result
for scheme \(C\), although the result is rather obvious, if not trivial.

The following lemma reveals the semantical intention of ma-
trix decomposition (cf. Section 2.2). For instance, specialization
\(S(c, P \rightarrow A)\) expresses exactly what remains to be matched, once
it is known that \(v_1\) admits \(c\) as a head constructor.

**LEMMA 1** (Key properties of matrix decompositions). Let \(P \rightarrow A\) be a clause matrix.

1. For any constructor \(c\), the following equivalence holds:
   \[ \text{Match}[(c, w_1, \ldots, w_n) v_2 \cdots v_n, P \rightarrow A] = k \]
   \[ \text{Match}[(w_1, \ldots, w_n) v_2 \cdots v_n, S(c, P \rightarrow A)] = k \]
   Where \(w_1, \ldots, w_n\) and \(v_2, \ldots, v_n\) are any values of appropriate
types.

2. Let now \(c\) be a constructor which does not appear as a head
constructor of the patterns of the first column of \(P\) (i.e. \(c \not\in \Sigma_1\)).
   For all values \(w_1, \ldots, w_n, v_2, \ldots, v_n\) of appropriate types, we have the equivalence:
   \[ \text{Match}[(c, w_1, \ldots, w_n) v_2 \cdots v_n, P \rightarrow A] = k \]
   \[ \text{Match}[(v_2 \cdots v_n), D(P \rightarrow A)] = k \]

**Proof:** Mechanical application of definitions. Q.E.D.

**PROPOSITION 1.** Let \(P \rightarrow A\) be a clause matrix. Then we have:

1. If for some value vector \(\vec{v}\), we have \(\text{Match}[\vec{v}, P \rightarrow A] = k\),
   then for all decision trees \(A = \text{CC}(P \rightarrow A)\), we have \(\vec{v} \vdash A \iff k\).

2. If for some value vector \(\vec{v}\) and decision tree \(A = \text{CC}(P \rightarrow A)\)
   we have \(\vec{v} \vdash A \iff k\), then we have \(\text{Match}[\vec{v}, P \rightarrow A] = k\).

**Proof:** Consequence of the previous lemma and by induction over
\(A\) construction. Q.E.D.

It is to be noticed that the non-determinism of \(C\) has no semantical
impact: whatever column choices are, the produced decision trees
have the same semantics, i.e. they faithfully implement ML matching.

6. Examples
Let us consider a very commonly found pattern matching expres-
sion, which any match compiler should probably compile opti-
mally.

**EXAMPLE 1.** The classical merge of two lists:

\[
\text{let rec merge} = \text{match} \begin{cases} \text{xs}, \text{ys} \\ \text{ys}, \text{xs} \end{cases} \text{ with} \\
| [], \_ \rightarrow \text{ys} \\
| \_, [\_] \rightarrow \text{xs} \\
| x::rx, y::ry \rightarrow \ldots \\
\]

![Figure 3. Compilation of list-merge, left-to-right](image)

Focusing on pattern matching compilation, we only consider the
following “occurrence” vector\(^2\) and clause matrix.

\[
\delta = (x_1 y_2) \quad P \rightarrow A = \begin{pmatrix}
- & \_ & \_ & \rightarrow 1 \\
- & \_ & \_ & \rightarrow 2 \\
- & \_ & \_ & \_ & \rightarrow 3
\end{pmatrix}
\]

The compiler now has to choose a column to perform matrix de-
composition. That is, the resulting decision tree will either exam-
ine \(x_1\) first or \(y_2\) first.

Let us first consider examining \(x_1\). We have \(\Sigma_1 = \{ :, :, \}\),
a complete signature. We need not consider the default matrix, and we get:

\[
\text{CC}((x_1 y_2), P \rightarrow A) = \text{Switch}_{x_1}((::):A_1; (:)A_2)
\]

Where:

\[
A_1 = \text{CC}((x_1-1 x_2 y_2), S((::), P \rightarrow A))
\]
\[
A_2 = \text{CC}(y_1, S((), P \rightarrow A))
\]

The rest of compilation is deterministic. Let us consider for instance \(A_1\). We have (section 2.2):

\[
S((::), P \rightarrow A) = \begin{pmatrix}
- & \_ & \_ & \rightarrow 2 \\
- & \_ & \_ & \_ & \rightarrow 3
\end{pmatrix}
\]

Only the third column has non-wildcards, hence we get (by compila-
tion step 3, then 2)

\[
A_1 = \text{Swap}_y (\text{Switch}_{x_1}((::):\text{Leaf}(3); ()\text{Leaf}(2)))
\]

Computing \(A_2\) is performed by a direct application of step 2:

\[
S((), P \rightarrow A) = \begin{pmatrix}
- & \_ & \_ & \rightarrow 1
\end{pmatrix}
\]

\[
A_2 = \text{Leaf}(1)
\]

The resulting decision tree is best described as the picture of Fig-
ure 3. We now consider examining \(y_2\) first. That is, we swap the
two columns of \(\delta\) and \(P\), yielding the new arguments:

\[
\delta' = (y_2 x_1) \quad P' \rightarrow A = \begin{pmatrix}
- & \_ & \_ & \rightarrow 1 \\
- & \_ & \_ & \_ & \rightarrow 2 \\
- & \_ & \_ & \_ & \_ & \rightarrow 3
\end{pmatrix}
\]

Specialized matrices are as follows:

\[
S((::), P' \rightarrow A) = \begin{pmatrix}
- & \_ & \_ & \rightarrow 1
\end{pmatrix}
\]
\[
S((), P' \rightarrow A) = \begin{pmatrix}
- & \_ & \_ & \rightarrow 2
\end{pmatrix}
\]

Finally, compilation yields the decision tree of Figure 4. Notice that
the leaf “1” is pictured as shared, reflecting implementation with
maximal sharing. The pictures clearly suggest that the left-to-right
decision tree is better than the right-to-left one, in two important
aspects.

---

\(^2\)In examples, root occurrences are replaced by names, formally we can
define \(xs\) to be occurrence \(1\) and \(ys\) to be occurrence \(2\).
In this simple case, all decision trees are available and can be compared. A compiler cannot rely on such a post-mortem analysis, which can be extremely expensive. Instead, a compilation heuristic will select a column in $P$ at every critical step 3, based upon properties of matrix $P$. Such properties should be simple, relatively cheap to compute and have a positive impact on the quality of the produced decision tree.

Before we investigate heuristics any further, let us consider an example that illustrates the implementation of decision trees by dags with maximal sharing.

**Example 2.** Consider the following matching expression where $[\cdot]$ is OCaml pattern for “a list of one element” (i.e. $\ldots :: [\cdot]$.)

$$\text{match } xs, ys \text{ with } [\cdot], \ldots \rightarrow 1 \mid [\cdot], [\cdot] \rightarrow 2$$

Naive compilation of the example yields the decision tree that is depicted as a dag with maximal sharing in Figure 5. The dag of Figure 5 has $2+2 = 2$ switch nodes, where a plain tree implementation has $2 + 2 \times 2 = 6$ switch nodes. Now consider a simple generalization: a “diagonal” pattern matrix, of size $n \times n$ with $p_{ij} = [\cdot]$ and $p_{ij} = _-$ for $i \neq j$. It is not difficult to see that the dag representation of the naive decision tree has $2n$ switch nodes, where the plain tree representation has $2^n - 2$ switch nodes. Or-pattern compilation also benefits from maximal sharing. Let us consider for instance the $n$-tuple pattern $(1|2), \ldots, (1|2)$, of which compilation produces a tree with $2^n - 1$ switches and a dag with $2n$ switches. One may also remark that, for a clause matrix of one row, of which some patterns are or-patterns, maximal sharing makes column choice indifferent. While, without maximal sharing, or-patterns should better be expanded last. As a conclusion, maximal sharing is a simple idea that may yield important savings in code size.

Finally, here is a more a realistic example, where maximal sharing does not help.

**Example 3.** This example is extracted from a bytecode machine for PCF (Plotkin 1977) (or mini-ML). Transitions of the machine depend upon the values of three items: accumulator $a$, stack $s$ and code $c$. The heart of a ML function that implements the machine consists in the following pattern matching expression:

```ocaml
let rec run a s e c = match a, s, e with
    | __, __, __, c -> 1
    | __, Push :: c -> 2
    | Int n2, Val (Int n1) :: s, DOp op :: c -> 3
    | Int 0, __, Test (c2, _) :: c -> 4
    | Int __, Test (__, c3) :: c -> 5
    | __, Extend :: c -> 6
    | __, Search k :: c -> 7
    | __, Pushenv :: c -> 8
    | _, Env e :: s, Popenv :: c -> 9
    | __, Mklclos cc :: c -> 10
    | __, Mklclosrec cc :: c -> 11
    | Clo (cc, ce), Val v :: s, Apply :: c -> 12
    | a, (Code c :: Env e :: s), [ ] -> 13
    | a, [ ], [ ] -> 14
```

Compiling the example naively yields the decision tree of Figure 6. There is no sharing, except at leaves. For the sake of clarity, all leaves are omitted, except Leaf(4). There are 56 switches in the decision tree of Figure 6. As to runtime efficiency, all paths to Leaf(4), are emphasized, showing that it takes between 5 and 8 tests to reach action 4. Figure 7 gives another decision tree, which we constructed by systematic exploration of column choices. The size of the resulting tree (17 switches) is thus guaranteed to be minimal (as a tree not as a dag with maximal sharing). The tree of Figure 7 is also more efficient at runtime: it takes only 4 tests for it to reach action 4.

It is in fact not difficult to produce the minimal tree by local column choices only: the first initial choice should be of examining $c$, then a second choice should be of examining $e$ if $c$ is a non-empty list. In both cases, the right choice can be made by selecting a column $i$ such that no pattern $p_{ij}$ is a wildcard for $1 \leq j \leq m$. In the rest of the paper we generalize the idea, and then experimentally check its validity.

7. **Necessity**

Figures 3 and 4 give all the possible decision trees that result from compiling example 1. Now, let us examine the paths from root to leaves. In both trees, all paths to Leaf(2) and Leaf(3) traverse two switch nodes. By contrast, the paths to Leaf(1) traverse one switch node in the tree of Figure 3 and two switch nodes in the tree of Figure 4. We can argue that the first tree is better because it has shorter paths. Furthermore, we remark that $xs$ is tested by all paths to Leaf(1), while $ys$ is not.

A path in a decision tree is an ordinary path from root to leaf. When a path traverses a node Switch,($c$) we say that the path tests the occurrence $o$.

**Definition 2 (Necessity).** Let $P$ be a pattern matrix. Let $\bar{o}$ be the conventional occurrence vector, s.t. $o_i = i$, and let $A$ be the conventional action vector, s.t. $a^j = j$. Column $i$ is needed for row $j$ when all paths to leaf $\text{Leaf}(j)$ in all decision trees $CC(\bar{o}, P \rightarrow A)$ test occurrence $i$. If column $i$ is needed for all rows $j$, $1 \leq j \leq m$, column $i$ is needed (for matching by $P$).

Necessity-based heuristics will favor needed columns over non-needed ones, based upon the simple idea to perform immediately work that need to be performed anyway. From this idea, we expect decision trees with shorter paths. Additionally, we may expect that decision trees with shorter paths also are smaller. In the list-merge

![Figure 5. Decision tree as a dag with maximal sharing](image)

![Figure 4. Compilation of list-merge, right-to-left](image)
Figure 6. Naive decision tree for example 3

Figure 7. Minimal decision tree for example 3
example the following matrix summarizes necessity information:

\[ N = \begin{pmatrix} \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots \end{pmatrix} \]

Where \( n_i^j = \bullet \), if and only if column \( i \) is needed for row \( j \). It is intuitively clear (and we shall prove it), that if \( n_i^j = \bullet \) is a constructor pattern, then \( n_i^j = \bullet \). However, this is not a necessary condition since we also have \( n_i^j = 0 \). It is worth observing that, here, column 1 is needed, and that by selecting it we produce a decision tree with optimal path lengths (and optimal size).

More generally we can make the following two remarks:

1. If we discover a needed column at every critical compilation step 3 and follow it, then compilation will produce a decision tree with optimal path length.

2. Let a column made of constructor patterns only be a strongly needed column. If at every critical compilation step 3, we discover a strongly needed column and follow it, then the resulting decision tree will possess no more switch nodes than the number of constructors in the original patterns.

Remark (1) is a corollary of Definition 2, while remark (2) follows from the definition of matrix decomposition (Section 2.2). Of course, the remarks are not sufficient when several or no needed columns exist. In any case, necessity looks an interesting basis for designing heuristics.

The rest of this section explains how to compute necessity from matrix \( P \).

### 7.1 Computing necessity

The first step in our program is to relate the absence of a switch node on a given occurrence to decision tree evaluation. To that aim, we slightly extend our semantics of pattern matching. We define a supplementary value \( \xi \) (reading "crash"), and consider extended value vectors \( \vec{v} \) of which exactly one component is \( \xi \). That is, there exists an index \( \omega \), with \( v_\omega = \xi \) and \( v_i \neq \xi \) for \( i \neq \omega \).

The semantics of decision tree evaluation (Fig. 2) is left unchanged. As a result, if top of stack \( v_1 \) is \( \xi \) then the evaluation of \( \text{Switch}_{v_0}(L) \) is blocked. We rather express the inverse situation:

**Lemma 2.** Let \( P \rightarrow A \) be a clause matrix with at least one column \((n > 0, m > 0) \). Let \( \vec{v} \) be a vector of pairwise incompatible occurrences. Let finally \( A = \text{CC}(\vec{v}, P \rightarrow A) \) be a decision tree. Then we have the equivalence: there exist an extended vector \( \vec{v}' \) with \( v_\omega = \xi \) and an action \( a \) such that \( \vec{v} \vdash A \nrightarrow k \), if and only if \( A \) possesses a path to Leaf \( k \) that does not test \( v_\omega \).

**Proof:** By induction on the construction of \( A \).

1. The case \( m = n = 0 \) is excluded by hypothesis.

2. If the first row of \( P \) consists of wildcards, then we have \( A = \text{Leaf}(a)^1 \). Then observe, on the one hand, that for any (extended) value vector \( \vec{v} \), we have \( \vec{v} \vdash A \nrightarrow a^1 \) (rule MATCH, Fig 2); while, on the other hand, the only path to \( \text{Leaf}(a)^1 \) is empty and thus does not traverse any \( \text{Switch}_{v_0}(\cdots) \) node.

3. \( A \) is produced by induction. There are two subcases.

   (a) If \( A \) is \( \text{Switch}_{v_0}(\vec{L}) \). We first prove implication. That is, we assume the existence of an extended vector \( \vec{v} \), with \( v_\omega = \xi \) and \( \vec{v} \vdash A \nrightarrow k \). Then, by the semantics of decision trees (rule SWITCHCONSTR or SWITCHDEFAULT from Fig 2), we have \( v \neq 1 \) and there exists a decision tree \( A' \) from the clause list \( \vec{L} \) and a value vector \( \vec{v}' \), such that \( \vec{v}' \vdash A' \nrightarrow k \). By construction of \( A \), the decision tree \( A' \) is \( \text{CC}(\vec{v}', Q \rightarrow B) \), where \( Q \rightarrow B \) is a decomposition (defined in Section 2.2) of \( P \rightarrow A \). From \( \omega \neq 1 \), vector \( \vec{v}' \)

   is an extended vector, that is there exists an unique index \( \omega' \), with \( v_\omega' = \xi \). Moreover, \( \omega' = \xi \). If \( Q \rightarrow B \) is the specialization \( \text{S}(c, P \rightarrow A) \), or \( \omega' = \xi \). Then we have \( \omega \neq 1 \), since \( A \) starts by testing \( v_0 \). The path goes on in some of \( A \) child, written \( A' = \text{CC}(\vec{v}', Q \rightarrow B) \), as we already have defined above — in particular there exists \( \omega' \), with \( v_\omega' = o_\omega \). By induction there exists \( \vec{v}' \) (whose size \( o' \) is the width of \( Q \)), with \( v_\omega' = \xi \) and \( \vec{v}' \vdash A' \nrightarrow k \). We then construct \( \vec{v} \) with \( v_\omega = \xi \) and \( \vec{v} \vdash A \nrightarrow k \) and thus conclude. Exact \( \vec{v} \) depends on the nature of \( Q \rightarrow B \). If \( Q \rightarrow B \) is the specialization \( \text{S}(c, P \rightarrow A) \), we define \( \vec{v} \) as \( (c(v_1', \ldots, v_{\omega'-1}', v_{\omega'}', \ldots, v_m')) \). Here we have \( \omega = \omega' - n - 1 \), noticing that we have \( \omega' > \alpha \) (from \( o_\omega' = o_\omega \)). Otherwise, \( Q \rightarrow B \) is the default matrix and there exists a constructor \( c \) that does not appear in \( L \). Then, we construct \( \vec{v} \) as \( (c(w_1', \ldots, w_n', v_1', \ldots, v_{\omega'-1}') \). Clearly, we have \( p_1 \leq \xi \) and \( p_1 \vdash A \nrightarrow k \), or the existence of a path that does not test \( o_\omega \) both imply \( \omega \neq 1 \).

   (b) If \( A \) is Swap \( (A') \) where \( A' = \text{Switch}_{v_0}(\vec{L}) = \text{CC}(\vec{v}', Q \rightarrow A) \), the arguments \( \vec{v}' \) and \( Q \) being \( \vec{o} \) and \( P \) with columns 1 and \( i \) swapped. We can conclude by induction, having first observed that assuming either the existence of \( \vec{v} \) with \( v_\omega = \xi \) and \( \vec{v} \vdash A \nrightarrow k \), or the existence of a path that does not test \( v_\omega \) both imply \( \omega \neq 1 \).

Q.E.D.

The second step of our technique to compute necessity is to relate decision tree evaluation and matching for extended values. By contrast with decision tree semantics, which we left unchanged, we slightly alter matching semantics. The instance relation \( \preceq \) is extended by adding the following two rules to the rules of section 2.1:

\[
(p_1 \preceq p_2) \quad \text{iff} \quad p_1 \leq \xi
\]

Clearly, we have \( p \preceq \xi \) if, and only if \( p \) is a non-generalized constructor pattern, that is, given our convention of simplifying \((\cdot) \) as \( \cdot \) in a preprocessing phase, if and only if \( p \) is a wildcard. The two rules above are the only extensions performed, in particular \( p \not\preceq \xi \) never holds, whatever pattern \( p \) is. It is then routine to extend definition 1 of ML matching and also lemma 1 (key properties of decompositions).

We now alter the correctness statement of compilation (Proposition 1) so as to handle extended values.

**Lemma 3.** Let \( P \rightarrow A \) be a clause matrix. The following two implication hold:

1. If there exists an extended value vector \( \vec{v} \) such that \( \text{Match} [\vec{v}, P \rightarrow A] = k \), then there exists a decision tree \( A = \text{CC}(P \rightarrow A) \) such that \( \vec{v} \vdash A \nrightarrow k \).

2. If for some extended value vector \( \vec{v} \) and decision tree \( A = \text{CC}(P \rightarrow A) \) we have \( \vec{v} \vdash A \nrightarrow k \), then we also have \( \text{Match} [\vec{v}, P \rightarrow A] = k \).

**Proof:** Proposition 1 above differs significantly from the corresponding Proposition 1-1, since existential quantification replaces universal quantification. In other words, if an extended value
matches some row in \( P \), then all decision trees may not be correct, but there is at least one so. We prove proposition 1 by induction over the structure of \( P \).

1. The case \( m = n = 0 \) is impossible, since then \( P \) has no row at all, and hence no row that can filter values.
2. If the first row of \( P \) consists in wildcards. Then \( A \) must be \( \text{Leaf}(a^1) \) and is appropriate.
3. Otherwise, by hypothesis there exists an extended vector \( \vec{v} \) \((v_m = \dagger)\) that matches some row of \( P \) in the ML sense. We first show the existence of a column index \( i \), such that \( i \neq \omega \) and that one of the patterns in column \( i \) is a generalized constructor pattern. There are two cases to consider.
   (a) If \( \vec{v} \) matches the first row of \( P \), then, \( p^1 \preceq \vec{v} \). Because, we are in the “otherwise” case, there exists a column index \( i \) such \( p^1_i \) is not a wildcard. By the extended definition of \( \preceq \) we have \( i \neq \omega \).
   (b) If \( \vec{v} \) matches some row of \( P \) other than the first row, then, by definition of ML matching, we have \( p^1 \neq \vec{v} \). Thus, by definition of \# on vectors, there exists a column index \( i \), such \( p^1_i \neq v_i \). Since \( p^1 \neq \vec{v} \) never holds, we have \( v_i \neq \dagger \) (and thus \( i \neq \omega \)). Furthermore, \( p^1_i \) is a generalized constructor pattern, since, for any value \( w \), \((q_1 q_2) \# w \) implies \( q_1 \# v \); and that \( \# w \) never holds.

Now that we have found \( i \) such that \( p^1_i \) is not a wildcard, compilation can go on by decomposition along column \( i \). Additionally, we know (from \( v_i \neq \dagger \) ) that there exists a constructor \( c \), with \( v_1 = c(w_1, \ldots, w_n) \).

(a) If \( i \) equals 1. Then, there are then two subcases, depending on whether \( c \) is the head constructor of one of the patterns in the first column of \( P \) or not (i.e. \( c \in \Sigma_1 \) or not). Let us first assume \( c \in \Sigma_1 \). Then, by lemma 1-1, we construct \( \vec{v}' = (w_1 \ldots w_n v_2 \ldots v_n) \), such that \( \text{Match}(\vec{v}'; S(c, P \to A)] \equiv k \). Notice that \( \vec{v}' \) is an extended value vector. Hence, by induction, there exists a decision tree \( A' \) with \( \vec{v}' \vdash A' \). It remains to compile the other decompositions of \( P \) in any manner, to regroup them in a clause list \( L \) and to define \( A = \text{Switch}(L) \). The case where \( c \notin \Sigma_1 \) is similar, considering \( \vec{v}' = (v_2 \ldots v_n) \) and the default matrix.

(b) If \( i \) differs from 1. We first swap columns 1 and \( i \) in both \( \vec{v} \) and \( P \). Then, we can reason as above.

We omit the proof of proposition 2., which is by induction over the structure of \( P \), using lemma 1 in the other direction. Q.E.D.

Finally, one easily relates matching of extended values and matching of ordinary variables.

**Lemma 4.** Let \( P \) be a pattern matrix with rows and columns \((m > 0, n > 0)\). Let \( \vec{v} \) be an extended vector \((v_m = \dagger)\), then row \( j \) of \( P \) filters \( \vec{v} \), if and only if:

1. Pattern \( p^1_i \) is not a generalized constructor pattern.
2. And row \( j \) of matrix \( P/\omega \) filters \((v_1 \ldots v_{\omega-1} v_{\omega+1} \ldots v_n)\), where \( P/\omega \) is \( P \) with column \( \omega \) deleted:

\[
P/\omega = \begin{pmatrix}
p_{11} & \cdots & p_{1m} \\
p_{21} & \cdots & p_{2m} \\
\vdots & \ddots & \vdots \\
p_{n1} & \cdots & p_{nm}
\end{pmatrix}
\]

**Proof:** Corollary of Definition 1 (ML matching). Q.E.D.

Finally, we reduce necessity to usefulness. By “usefulness” we here mean the usual usefulness diagnosed by ML compilers.

**Proposition 2.** Let \( P \) be a pattern matrix. Let \( i \) be a column index and \( j \) be a row index. Then, column \( i \) is needed for row \( j \), if and only if one of the following two (mutually exclusive) propositions hold:

1. Pattern \( p^1_i \) is a generalized constructor pattern.
2. Or, pattern \( p^1_i \) is a wildcard, and row \( j \) of matrix \( P/\omega \) is useless.

**Proof:** Corollary of the previous three lemmas. Q.E.D.

Consider again the example of list merge:

\[
P \to A = \begin{pmatrix}
\dagger & \# & \dagger \\
\dagger & \# & \dagger
\end{pmatrix}
\]

From the decision trees of Figures 3 and 4 we found that column 1 is needed for row 2. The same result follows by examination of the matrix \( P/1 \):

\[
P/1 = \begin{pmatrix}
\dagger \\
\dagger
\end{pmatrix}
\]

Obviously, the second row of \( P/1 \) is useless, because of the initial wildcard. One could also have considered matrix \( P \) directly, remarking that no extended value vector \( \vec{v} = (j v_2) \) matches the second row of \( P \), because \((\dagger \dagger) \# (j v_2) \) implies \( \dagger \dagger \dagger \), which is impossible.

Here is a slightly more subtle example.

**Example 4.** Let \( P \) be the following occurrence vector and pattern matrix.

\[
\vec{v} = (x \ y) \quad P = \begin{pmatrix}
\text{true} & 1 \\
\text{false} & 2
\end{pmatrix} \quad N = \begin{pmatrix}
\cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot
\end{pmatrix}
\]

\( N \) is the necessity matrix.

The first two rows of \( N \) are easy, because all the corresponding patterns in \( P \) are constructor patterns. To compute the third row of \( N \) it suffices to consider the following matrices:

\[
P/1 = \begin{pmatrix}
1 \\
2
\end{pmatrix} \quad P/2 = \begin{pmatrix}
\text{true} \\
\text{false}
\end{pmatrix}
\]

The third row of \( P/1 \) is useful, since it filters value 3 for instance; while the third row of \( P/2 \) is useless, since \{true, false\} is a complete signature. Hence the necessity results for the third row: column \( x \) is not needed, while column \( y \) is. These results are confirmed by examining the paths to \( \text{Leaf}(3) \) in the two decision trees of Figure 8. One may argue that the second tree is better, since action 3 is reached without testing \( x \) when \( y \) differs from 1 and 2.

As regards the computation of usefulness. It should probably first be said that the usefulness problem is NP-complete (Sekar et al. 1995). Nevertheless, our algorithm (Maranget 2007) for computing usefulness has been present in the OCaml compiler for years, and has proved efficient enough for input met in practice. The algorithm is inspired by compilation to decision trees, but is much more efficient, in particular as regards space consumption and in situations where a default matrix is present.

**8. Heuristics**

**8.1 Heuristic definitions**

We first recall the heuristics selected by Scott and Ramsey (2000), which we adapt to our setting by considering generalized constructor patterns in place of constructor patterns. We identify each heuristics by a single letter (\( f, d, \) etc.) Each heuristic can be defined as a score function, (also written \( f, d, \) etc.) from column indices

\[3\text{“redundant”, in the terminology of Milner et al. (1990).} \]
to integers, with the heuristics selecting columns that maximize the score function. As regards the inventors and justifications of heuristics we refer to Scott and Ramsey (2000), except for the first row heuristic below, which we understand differently.

**First row f** Heuristic f favors columns i such that pattern \( p_i^f \) is a generalized constructor pattern. In other words the score function is \( f(i) = 1 \) in the first case, and \( f(i) = 0 \) in the second case.

Heuristic f is based upon the idea that the first pattern row has much impact on the final decision tree. More specifically, if \( p_i^f \) is a wildcard and that column \( i \) is selected for compilation, then there will be an action \( a_i \) in all decompositions, and this clause will always be useful, since it is in first position. As a result, every child of the emitted switch includes at least one Leaf\((a^i)\) leaf and a path to it. Selecting \( i \) such that \( p_i^f \) is a constructor pattern results in the more favorable situation where only one child includes Leaf\((a^i)\) leaves. In Baudinet and MacQueen (1985) the first row heuristic is described in a more complex way and called the "relevance" heuristic. From close reading of their descriptions, we believe our simpler presentation to yield the same choices of columns, except, perhaps, for the marginal case of signatures of size 1 (e.g., pairs).

**Small default d** Given a column index \( i \) let \( v(i) \) be the number of wildcard patterns in column \( i \). The score function d is defined as \(-v(i)\).

**Small branching factor b** Let \( \Sigma_i \) be the set of the head constructors of the patterns in column \( i \). The score \( b(i) \) is the opposite of the cardinal of \( \Sigma_i \), minus one if \( \Sigma_i \) is not a complete signature. In other words, \( b(i) \) is the opposite of the number of children of the Switch\(_o\)(L) node that is emitted by the compiler when it selects column \( i \).

**Arity a** The score \( a(i) \) is the opposite of the sum of the arities of the constructors of the \( \Sigma_i \) set.

**Leaf edge \( \ell \)** The score \( \ell(i) \) is the number of the children of the emitted Switch\(_o\)(L) node that are Leaf\((a^k)\) leaves. This information can be computed naively, by first swapping columns 1 and \( i \), then decomposing \( P \), (i.e., computing all specialized matrices, and the default matrix if applicable), and finally counting the decomposed matrices whose first rows are made of wildcards.

**Rows r** (Fewer child rule) The score function \( r(i) \) is the opposite of the total number of rows in decomposed matrices. This information can be computed naively, by first swapping columns 1 and \( i \), then decomposing \( P \), and finally counting the numbers of rows of the resulting matrices.

We introduce three novel heuristics based upon necessity.

**Needed columns n** The score \( n(i) \) is the number of rows \( j \) such that column \( i \) is needed for row \( j \). The intention is quite clear: locally maximize the number of tests that are really useful.

**Needed prefix p** The score \( p(i) \) is the larger row index \( j \) such that column \( i \) is needed for all the rows \( j' \), \( 1 \leq j' \leq j \). As the previous one, this heuristics tends to favor needed columns. However, it further considers that earlier clauses (i.e. the ones with higher priorities) have more impact on decision tree size and path lengths than later ones.

**Constructor prefix q** This heuristics derives from the previous one, approximating "column \( i \) is needed for row \( j' \)" by "\( p_i^f \) is a generalized constructor pattern". There are two ideas here: (1) avoid all uselessness computations; and (2) if column \( i \) is selected, any row \( j \) such that \( p_i^f \) is a wildcard is copied. Then, the others patterns in row \( j \) may be compiled more than once, regardless of whether column \( i \) is needed or not. Heuristic q can also be seen as a generalization of heuristic f.

Observe that heuristic d is a similar approximation of heuristic n.

It should be noticed that if matrix \( P \) has needed columns, then heuristics n and p will select those and only those. Similarly, if matrix \( P \) has strongly needed columns, then heuristics d and q will select those and only those. Heuristics n and p will also favor strongly needed columns but they will not distinguish them from other needed columns.

### 8.2 Combining heuristics

By design, heuristics always select at least one column. However, a given heuristic may select several columns, leaving ties unbroken. Ties are broken first by composing heuristics. For instance, Baudinet and MacQueen (1985) seem\(^4\) to recommend the successive application of f, b, and a, which we write fba. As an example consider a variation on matrix of example 4.

\[
P = \begin{pmatrix}
  \text{true} & 1 & \text{false} & 2 & 0 \\
  - & - & - & - & -
\end{pmatrix}
\]

Heuristic f selects columns 1 and 2, amongst those heuristic b selects column 1. Column selection being over, there is no need to apply heuristic a. The combination of heuristics is a simple means to construct sophisticated heuristics from simple ones. It should be noticed that combination order does matter, since an early heuristic may eliminate columns that a following heuristics would need.

Even when combined, heuristics may not succeed in selecting an unique column — consider a matrix with identical columns. We thus define the following three, last-resort, "heuristics".

**Pseudo-heuristics N, L and R** These select one column \( i \) amongst many, by selecting the minimal \( o_i \) in vector \( \ell \) according to various total orderings on occurrences. Heuristic N uses the leftmost ordering (this is naive compilation). Heuristics L and R

---

\(^4\)The description of Baudinet and MacQueen (1985) is a bit ambiguous.
first select shorter occurrences, and then break ties left-to-right or right-to-left, respectively. In other words, L and R are two variations on breath-first ordering of the subterms of the subject value.

Varying the last-resort heuristic permits a more accurate evaluation of heuristics.

9. Performance
9.1 Methodology
We have written a prototype compiler that accepts pattern matrices and compiles them with various match compilers. The implemented match compiler includes compilation to decision tree, both with and without maximal sharing and the optimizing compiler of Lef
cass and Maranget (2001), which we shall adopt as a reference. The prototype compiler targets matching automata, expressed as a simplified version of the intermediate language of the OCaml compiler (Leroy et al. 2007). This target language features local bindings, indexed memory reads, switches, and local functions. Local functions implement maximal sharing or backtracking, depending upon the compilation algorithm enabled. We used the prototype to produce all the pictures in this paper, switch nodes being pictured as internal nodes, variables binding memory read expressions being used to decorate switch nodes, local function definitions being rendered as nodes with several ingoing edges.

The performance of matching automata is estimated as follows:

1. Code size is estimated as the total number of switches.
2. Runtime performance is estimated as average path length. Ideally, average path length should be computed with respect to some distribution of subject values that is independent of the automaton considered. In practice, we compute average path length by assuming that: (1) all actions are equally likely; and (2), all constructors that can be found by a switch are equally likely.

To feed the prototype, we have extracted pattern matching expressions from a variety of OCaml programs, including the OCaml compiler itself, the Coq and Why proof assistants (Coq; Filli
tre 2008), and the Cil infrastructure for C program analysis (Neculla et al. 2007). The selected matching expressions were identified by a modified OCaml compiler that performs match compilation by several algorithms and signal differences in number of switch generated — more specifically, we used OCaml match compiler and make CC without sharing.

We finally have selected 54 pattern matching expressions, attempting to vary size and programming style (in particular, 35 expressions do not include or-patterns). The test of an heuristic consists in compiling the 54 expressions twice, ties left by the heuristic being broken by the pseudo-heuristics L and R. Each of these 108 compilations produces two data: automata size and average path length. We then compute the geometric means of data, considering ratios with respect to OCaml match compiler (base 100.0). The final figures for testing heuristics individually are given by Table 1 that shows results rounded to the nearest integer.

Results first demonstrate that maximal sharing is mandatory for decision tree to compete with (optimized) backtracking automata as regards code size. Even more, with heuristics q,p and f, decision trees win over (optimized) backtracking automata. As regards path length, decision trees always win, with necessity heuristics p, q and n, yielding the best performance, heuristic f being quite close. Overall, heuristic q and p are the winners, but no clear winners.

5Except for integers, where the default clause of a switch is considered as likely as other clauses.

For all cost measures, the pseudo heuristics that base their choice on fringe occurrences only (i.e. N, L and R) behave poorly. Thus, to improve performance, real heuristics that analyze matrix P are called for. As a side note, the results also show a small bias of our test set against left to right ordering.

9.2 Estimation of combined heuristics
We test all combinations of heuristics up to three heuristics, discarding a few combinations that obviously can be. For instance, qf and fq are equivalent to q. Overall, we test 507 combined heuristics. We attempt to summarize the results by the histograms of Table 2. The histograms show the distribution of results. For instance there are 12 combined heuristics that produce trees with sizes in the range 86–88. These are qb[a/r], fb[ad/r], fr, and f[r[ab/d/n]]. Classifying heuristics by performance ranges allows result presentation. Moreover, one has to consider that data depend on the test set and are only estimations of actual costs. Thus, it looks reasonable to replace exact figures by ranges.

The results show that combining heuristics yields significant improvements in size and little in path length. Good heuristics are the ones whose performance are in the best ranges for both size and path length. Unfortunately, no heuristic belongs to both ranges 86–88 for size and 84–88 for path length. We thus extend the acceptable size range to 86–90 and compute the intersection with the path length range 84–90. The process yields the unique champion heuristic pba. Intersecting size ranges 86–90 and path length range 84–88, yields 48 heuristics: fd[br], fnr, fr, f[r[ab/d/n]], qb, q[b[ad/nqr]], p[d][br], p[nr], q[p][br], pr, p[r[ab/d/nq]], qb, q[b[ad/nqr]], qdr, qr[nbr], q[p][br], qr, and q[r[ab/d/n]]. From those results, we draw a few conclusions:

1. Good primary heuristics are f, p and q. This demonstrates the importance of considering clause order in heuristics. Our personal choice is q. We tend to reject f because it does not detect strongly needed columns. Moreover, q is easier to compute than p and is the best heuristic when used alone.
2. If we limit choice to combinations of at most two heuristics, r is a good complement to all primary heuristics. Heuristic b looks sufficient to break the ties left by p and q.
3. If we limit choice to heuristics that are simple to compute, that is if we eliminate n, p, r and f, then good choices are fd, qb and q[b[ad]]. Amongst those, qba is the only one with size in the best range.

As a personal conclusion, our favorite heuristic is the champion pba. If one wishes to avoid usefulness computations, we view qba as a good choice. To be fair, heuristics that are or have been in use in the SML/NJ compiler are not far away. From our understanding of its source code, the current version of the SML/NJ compiler uses heuristic fd, earlier versions used fba. Heuristic fd is a good choice, while fba misses it by little, with size in the range 86–88 and path length in the range 88–90.

9.3 Relation with actual performance
We have integrated compilation to decision trees into the OCaml compiler.

Measuring the impact of varying pattern match compilation over actual code size and running time is a frustrating task. Consider, for instance, compiling the Coq system twice, with the match compiler of Le Fessant and Maranget (2001) and with CC guided by heuristic qba. Then, the sizes of binaries are virtually the same. Although some differences in the size of individual object files exist, those are not striking. More precisely out of 306 object file,
have identical sizes, and only 5 files have sizes that differ by 5% or more. This means that we lack material to analyze the impact of low level issues, such as how switches are compiled to machine code. Differences in running times are even more difficult to observe.

However, we cannot exclude the possibility of programs to which pattern matching matters. In fact we know of one such program: an interpreter that runs the bytecode machine of example 3. As with other programs, differences in code size are dwarfed by non-pattern matching code. Differences in speed are observable by interpreting small PCF terms that are easy to parse and compile, but that run for long. We test two such terms, resulting in the ratios of path lengths. Moreover, running times are indeed bad if heuristics are neglected, especially for compilation to bytecode.

### 10. Related work

Needed columns exactly are the directions of Laville (1988); Puel and Suárez (1989); Maranget (1992). All these authors build over lazy pattern matching. By building over strict pattern matching, our present work leads more directly to heuristics design. Strongly needed columns are the indices of Sekar et al. (1995), who prove that selecting strongly needed columns minimizes decision tree breadth (number of leaves) and path lengths. One may notice that the minimization result on path lengths smoothly extends to needed columns (a direct consequence of our definition).

Scott and Ramsey (2000) study heuristics experimentally. We improve on this work by testing more heuristics (i.e. the necessity-based heuristics) and also by considering or-patterns and maximal sharing. We also differ by an important detail in methodology: Scott and Ramsey (2000) count switch nodes and measure path lengths, as we do, but they do so for complete ML programs by instrumenting the SML/NJ compiler. As a result, their experiments are more expensive than ours, and they could not conduct complete experiments on combination of three heuristics. Furthermore, by our prototype approach, we restrict the test set to matchings for which heuristics make a difference. As a result, comparison of heuristics is easier to perform and we are able to recommend some heuristics. Of course, as regards the significance of our recommendations for actual compilation, we are in the same situation as Scott and Ramsey (2000): most often, heuristics do not make such a difference. However, according to some of the tests of Scott and Ramsey (2000) (machine instruction recognizers), heuristics do matter. It would be particularly interesting to test the effect of necessity heuristics and of maximal sharing on those matchings, which, unfortunately, are not available.

### 11. Conclusion

Compilation to decision trees with maximal sharing, when guided by a good column heuristic, matches the performance of an optimizing compiler to backtracking automata, and can do better on some examples. Moreover, an optimizing compiler to decision trees is easier to implement than our own optimizing compiler for backtracking automata (Le Fessant and Maranget 2001). Namely, maximal sharing and simple heuristics (such as qba) are orthogonal extensions of the basic compilation scheme CC, so that the resulting optimizing match compiler remains simple. In particular, maximal sharing can be implemented by the well established technique of hash-consing – see e.g. Filliâtre and Conchon (2006).
Designing optimizing match compilers that preserve more constrained semantics is an interesting direction for future research. In particular, a match compiler for Haskell must preserve the termination behavior of Augustsson (1985). Another example is the compilation of the active patterns of (Syme et al. 2006). To that aim, the match compiler of Sestoft (1996) may be a valid starting point, because its definition follows ML matching semantics very closely.
